

A note on complete hyperbolic structures on ideal triangulated 3-manifolds

Feng Luo

Dedicated to Bus Jaco on the occasion of his 70th birthday

ABSTRACT. It is a theorem of Casson and Rivin that the complete hyperbolic metric on a cusp end ideal triangulated 3-manifold maximizes volume in the space of all positive angle structures. We show that the conclusion still holds if some of the tetrahedra in the complete metric are flat.

1. Introduction

1.1. Epstein and Penner [1] proved that a non-compact finite volume complete hyperbolic 3-manifold has a geodesic triangulation in which each 3-simplex is a (possibly flat) ideal hyperbolic tetrahedron. Here a flat ideal hyperbolic tetrahedron is a tetrahedron with all dihedral angles being 0 and π . The purpose of this paper is to show that a geodesic ideal triangulation of a complete hyperbolic 3-manifolds with some flat tetrahedra maximizes the volume in the closure of the space of non-negative angle structures. In the case all tetrahedra are non-flat, this was proved by Casson and Rivin (see [2], [3] for a written proof). We remark that the corresponding result also holds for hyper-ideal geodesic triangulations of compact hyperbolic 3-manifolds with totally geodesic boundary. This will be addressed in another paper.

1.2. Recall that a triangulated closed pseudo 3-manifold (M^*, T^*) is the quotient of a disjoint union of tetrahedra so that co-dimension-1 faces are identified in pairs by affine homeomorphisms. The simplices in the triangulation T^* are the quotients of simplices in the disjoint union. If we remove all vertices of T^* from M^* , the result is an *ideal triangulated non-compact 3-manifold* (M, \mathbf{T}) . We say M has *cuspidal ends* if the link of each vertex in T^* is a torus or a Kleinbottle. We will deal with ideal triangulated cusp end manifolds (M, \mathbf{T}) in this paper. An *angle structure* on (M, \mathbf{T}) , introduced by Casson, Rivin and Lackenby ([7]), assigns each edge of each tetrahedron a positive number, called the angle, so that

- (1) the sum of three angles at edges from each vertex of each tetrahedron is π ,
and

(2) the sum of angles around each edge is 2π .

An *angled tetrahedron* is a tetrahedron so that each edge has assigned a positive number called the angle so that condition (1) above holds. Given an angled tetrahedron, there is a unique ideal hyperbolic tetrahedron, call the *geometric realization*, whose dihedral angles are the assigned angles. The volume of an angled tetrahedron is defined to be the volume of its geometric realization. The volume of an angle structure is the sum of the volume of its angled tetrahedra.

For an ideal triangulated 3-manifold (M, \mathbf{T}) with n tetrahedra, let $\mathbf{A}(\mathbf{T}) \subset \mathbf{R}^{6n}$ be the space of all angle structures on \mathbf{T} and let $vol : \mathbf{A}(\mathbf{T}) \rightarrow \mathbf{R}$ be the volume function. By the Lobachevsky-Milnor's formula for volume, the volume function extends continuously to $vol : \overline{\mathbf{A}(\mathbf{T})} \rightarrow \mathbf{R}$ where $\overline{\mathbf{A}(\mathbf{T})}$ is the (compact) closure of $\mathbf{A}(\mathbf{T})$ in \mathbf{R}^{6n} .

Theorem 1.1 (Casson-Rivin). *For an ideal triangulated cusped 3-manifold (M, \mathbf{T}) so that $\mathbf{A}(\mathbf{T}) \neq \emptyset$, a point $p \in \mathbf{A}(\mathbf{T})$ corresponds to a complete hyperbolic structure on M if and only if p is the maximum point of the volume function $vol : \mathbf{A}(\mathbf{T}) \rightarrow \mathbf{R}$.*

Since the space $\mathbf{A}(\mathbf{T})$ is non-compact, there is no guarantee that the maximum point of vol exists. Our main theorem generalizes theorem 1.1 in one direction.

Theorem 1.2. *For an ideal triangulated cusp end 3-manifold (M, \mathbf{T}) so that $\overline{\mathbf{A}(\mathbf{T})} \neq \emptyset$, if a point $p \in \overline{\mathbf{A}(\mathbf{T})}$ corresponds to a complete hyperbolic structure on M , then p is the maximum point of the volume function $vol : \overline{\mathbf{A}(\mathbf{T})} \rightarrow \mathbf{R}$. Furthermore, the point p is the unique maximum volume point in $\overline{\mathbf{A}(\mathbf{T})}$.*

In [4], Futer and Gueritaud found an example of (M, \mathbf{T}) so that $\mathbf{A}(\mathbf{T}) \neq \emptyset$ and the maximum point of vol on $\overline{\mathbf{A}(\mathbf{T})}$ does not correspond to a complete hyperbolic metric. (A similar example was also found by Luo-Zheng [5] by making five 2-3 moves on the standard triangulation of the figure-8 knot complement). This shows that theorem 1.2 cannot be improved to be a necessary and sufficient condition. We are curious if the uniqueness of the maximum volume on $\overline{\mathbf{A}(\mathbf{T})}$ is the sufficient condition for the completeness of the metric.

Theorem 1.2 will be proved in §2.

1.3. Acknowledgement. We thank D. Futer, F. Gueritaud and S. Tillmann for helpful conversations. The work is partially supported by the NSF.

2. Proof of Theorem 1.2

Let us begin with some notations and conventions. Let $\mathbf{R}_{>0} = \{x \in \mathbf{R} | x > 0\}$ and $\mathbf{R}_{\geq 0} = \{x \in \mathbf{R} | x \geq 0\}$. Given a set X , let $\mathbf{R}^X = \{f : X \rightarrow \mathbf{R}\}$ be the vector space of all functions from X to \mathbf{R} . The function $x \ln x : (0, \infty) \rightarrow \mathbf{R}$ is extended continuously to $[0, \infty) \rightarrow \mathbf{R}$ by setting $0 \ln 0 = 0$. Suppose (M, \mathbf{T}) is an ideal triangulated 3-manifold so that V , E and T are the sets of all (ideal) vertices, edges and tetrahedra. Let $I = \{(e, \sigma) \in E \times T | \text{edge } e \text{ is adjacent to the tetrahedron } \sigma\}$. An angle structure is a vector in the space \mathbf{R}^I satisfying a set of linear equations and linear inequalities. If $x \in \mathbf{R}^I$, we use x_i to denote $x(i)$. If $i = (e, \sigma) \in I$, we use $i > e$ and $i < \sigma$ to indicate the incident relation. Three distinct $i = (e_1, \sigma), j = (e_2, \sigma)$ and $k = (e_3, \sigma)$ in I so that e_1, e_2, e_3 are three edges from the same vertex in σ will be denoted by $\{i, j, k\} \in \Delta$. Finally, we use $(e, \sigma) \sim (e', \sigma)$ to indicate that e, e' are two opposite edges in the same tetrahedron σ . Using these notations, we have

$$A(\mathbf{T}) = \{x \in \mathbf{R}^I \mid (1), (2), (3) \text{ hold}\}$$

where

- (1) if $\{i, j, k\} \in \Delta$, $x_i + x_j + x_k = \pi$;
- (2) if $e \in E$, $\sum_{i \in I, i > e} x_i = 2\pi$;
- (3) $x_i > 0$ for all $i \in I$.

Note that condition (1) implies that $x_i = x_j$ when $i \sim j$. The closure $\overline{\mathbf{A}(\mathbf{T})}$ of $\mathbf{A}(\mathbf{T})$ is give by $\{x \in \mathbf{R}_{>0}^I \mid (1) \text{ and } (2) \text{ hold}\}$. Theorem 1.2 does not assume $\mathbf{A}(\mathbf{T}) \neq \emptyset$, but it assumes $\overline{\mathbf{A}(\mathbf{T})} \neq \emptyset$. Elements in $\overline{\mathbf{A}(\mathbf{T})}$ will be called *non-negative angle structures*.

Suppose σ is an angled tetrahedron with three angles x_1, x_2, x_3 at three edges from a vertex. Then the Lobachevsky-Milnor volume formula says the volume $vol(\sigma)$ of σ is $\Lambda(x_1) + \Lambda(x_2) + \Lambda(x_3)$ where $\Lambda(t) = -\int_0^t \ln |2 \sin(u)| du$ is the Lobachevsky function. The function $\Lambda(t)$ is continuous on $[0, \pi]$. In particular, the volume function $vol : \overline{\mathbf{A}(\mathbf{T})} \rightarrow \mathbf{R}$ is give by

$$(2.1) \quad vol(x) = \frac{1}{2} \sum_{i \in I} \Lambda(x_i).$$

Note that $vol(x) = \sum_{\sigma \in T} vol(\sigma)$ where σ is the angled tetrahedron with angles given by x .

2.1. Set up the proof. Assume that $p \in \overline{\mathbf{A}(\mathbf{T})}$ corresponds to the complete hyperbolic metric on M . If $p \in \mathbf{A}(\mathbf{T})$, then Casson-Rivin's theorem implies that p is the maximum point of the volume. It remains to deal with $p \in \partial \mathbf{A}(\mathbf{T}) = \overline{\mathbf{A}(\mathbf{T})} - \mathbf{A}(\mathbf{T})$. Take $q \in \overline{\mathbf{A}(\mathbf{T})}$ so that $q \neq p$. The goal is to show that $vol(p) > vol(q)$. To this end, let $f(t) = vol((1-t)p + tq)$ for $t \in [0, 1]$. We will show that $f(0) > f(1)$, i.e., $vol(p) > vol(q)$.

Lemma 2.1. *The function $f(t)$ is concave in $[0, 1]$ and is strictly concave in the open interval $(0, 1)$.*

PROOF. By a result of Rivin [9], the volume function $\Lambda(t_1) + \Lambda(t_2) + \Lambda(t_3)$ is strictly concave in the set $\{(t_1, t_2, t_3) \in \mathbf{R}^3 \mid t_1 + t_2 + t_3 = \pi, t_i > 0 \text{ for } i = 1, 2, 3\}$. In particular, this implies that the function $vol(x)$ is concave in $x \in \overline{\mathbf{A}(\mathbf{T})}$. Thus $f(t)$ is concave in $[0, 1]$. To see the strictly concavity, note that $vol(p) > 0$ since it is the volume of a complete hyperbolic structure. In particular, there is tetrahedron $\sigma \in T$ so that its angles in p are all positive. This implies that for $t \in (0, 1)$, the angles of σ in $(1-t)p + tq$ are positive. By Rivin's theorem, the volume $\sum_{i \in I, i < \sigma} \Lambda((1-t)p_i + tq_i)$ is strictly concave in $t \in (0, 1)$. Since $f(t)$ is the sum of concave functions in t so that one of them is strictly concave, it follows that $f(t)$ is strictly concave in $(0, 1)$. \square

For $t \in (0, 1)$, by the definition of the volume (2.1), we have

$$(2.2) \quad f'(t) = -\frac{1}{2} \sum_{i \in I} (q_i - p_i) \ln |2 \sin((1-t)p_i + tq_i)|$$

Note that we have used the convention that $0 \ln 0 = 0$ in (2.2). Indeed, if $p_i = q_i$ is 0 or π , then the term in (2.2) corresponding to i is defined to be 0. (This is due to the fact that $\Lambda(x) + \Lambda(y) + \Lambda(\pi - x - y) = 0$ if $x \in \pi \mathbf{Z}$.)

The goal is to show that

$$(2.3) \quad \lim_{t \rightarrow 0^+} f'(t) \leq 0.$$

Note that (2.3) and lemma 2.1 imply that $f(0) > f(1)$. In the rest of the subsections, we will focus on proving (2.3).

2.2. Let $J = \{i \in I \mid p_i = 0 \text{ or } p_i = \pi\}$. Note that if $(e, \sigma) \in J$, then $(e', \sigma) \in J$ for all other edges e' in σ by the definition of flat tetrahedron, i.e., all its dihedral angles are 0 or π . Let $a = q - p \in \mathbf{R}^I$.

Lemma 2.2. (1) If $\{i, j, k\} \in \Delta$, then $a_i + a_j + a_k = 0$, i.e., for each tetrahedron σ , $\frac{1}{2} \sum_{i < \sigma} a_i = 0$.
 (2) For each edge $e \in E$, $\sum_{i > e} a_i = 0$.
 (3) $\sum_{i \in I} a_i = 0$.

Indeed, the first two conditions follows from the definition of angle structures (1) and (2). The last condition follows from part (1) by summing over all tetrahedra and then divided by 2.

By lemma 2.2(3), we can rewrite $f'(t)$ in (2.2) as

$$(2.4) \quad f'(t) = -\frac{1}{2} \sum_{i \in I} a_i \ln |\sin((1-t)p_i + tq_i)|$$

The following was proved in [6]. It can also be found in [4].

Lemma 2.3.

$$(2.5) \quad \lim_{t \rightarrow 0^+} f'(t) = -\frac{1}{2} \left(\sum_{i \notin J} a_i \ln |\sin(p_i)| - \sum_{i \in J} a_i \ln |a_i| \right).$$

2.3. Penner's decorated ideal simplexes. To understand the right-hand-side of (2.5), we need a proposition about the geometry of decorated ideal hyperbolic tetrahedra. Following Penner [8], a *decorated ideal n-simplex* is an ideal hyperbolic n-simplex so that each vertex is assigned a horosphere centered at the vertex. If σ is a decorated ideal n-simplex and e is an edge of it, the length $L(e)$ of e is defined to be the signed distance between the two horospheres centered at the end points of e (the distance is negative if the horospheres intersect). More precisely, suppose p, p' are the two points of intersection of e with these two horospheres. Then $L(e)$ is $dist(p, p')$ if these two horospheres are disjoint and is $-dist(p, p')$ if they intersect.

Lemma 2.4. Suppose σ is a decorated ideal hyperbolic tetrahedron with edge length $L(e)$ and dihedral angle $\theta(e)$ at the edge e . Assume that $\theta(e) \in (0, \pi)$ for all edges. Then there is a constant $c(\sigma)$ depending only on σ so that for any pairs of opposite edges e, e' in σ ,

$$(2.6) \quad \frac{1}{2}(L(e) + L(e')) = \ln |\sin(\theta(e))| + c(\sigma)$$

PROOF. The proof is based on the cosine law for decorated ideal triangles first discovered by Penner [8]. Namely, give a decorated ideal triangle of lengths l_1, l_2, l_3 , the "angles" of the triangle, denoted by a_1, a_2, a_3 , are the lengths of the portion of the horocycle inside the triangle. Indices are arranged so that the angle a_i is facing the edge of length l_i . The the cosine law says

$$(2.7) \quad l_i = -(\ln a_j + \ln a_k) \quad \{i, j, k\} = \{1, 2, 3\}.$$

For the edge e (respectively e'), there are two face triangles of the tetrahedron σ having e (resp. e') as an edge. These face triangles are naturally decorated ideal hyperbolic triangles. Let a_1, a_2, a_3, a_4 (resp. a'_1, a'_2, a'_3, a'_4) be the inner angles of these decorated face ideal triangles so that a_i 's are adjacent to e (resp. e'). Let the rest of the four face angles (of the four decorated ideal triangles) be b_1, \dots, b_4 . Here vertices of angles b_i are either in e or e' . Then by the cosine law, we have

$$(2.8) \quad L(e) = -\frac{1}{2} \sum_{i=1}^4 \ln a_i \quad \text{and} \quad L(e') = -\frac{1}{2} \sum_{i=1}^4 \ln a'_i$$

This shows

$$\begin{aligned} L(e) + L(e') &= -\frac{1}{2} \sum_{i=1}^4 (\ln a_i + \ln a'_i) \\ &= \frac{1}{2} c_0(\sigma) + \frac{1}{2} \sum_{i=1}^4 \ln b_i \end{aligned}$$

where $c_0(\sigma) = \sum_{i=1}^4 (\ln a_i + \ln a'_i + \ln b_i)$ is the sum over all twelve face angles.

Consider the Euclidean triangles obtained by intersecting the horospheres with the ideal tetrahedron. The dihedral angles $\theta(e)$'s are the inner angles and the face angles b_i 's are the edge lengths of the Euclidean triangles. Thus, by the Sine law for Euclidean triangles, we can write

$$\ln b_i = c_i(\sigma) + \ln |\sin(\theta(e))|$$

where b_i has its vertex at e . Putting these together and using the fact that $\theta(e) = \theta(e')$, we obtain (2.6) where $c(\sigma) = \frac{1}{2} \sum_{i=0}^4 c_i(\sigma)$. \square

For a decorated ideal triangle of edge lengths $L(e)$, we define the *average edge length* of e to be $W(e) = \frac{1}{2}(L(e) + L(e'))$ where e, e' are opposite edges.

Lemma 2.5. *For a decorated ideal tetrahedron σ , if e_1, e_2, e_3 are three edges from a vertex v , then*

$$(2.9) \quad e^{W(e_1)} + e^{W(e_2)} \geq e^{W(e_3)}$$

so that equality holds if and only if $\theta(e_3) = \pi$, $\theta(e_1) = \theta(e_2) = 0$.

Indeed, consider the Euclidean triangle obtained by intersecting the horosphere centered at the vertex v with the ideal tetrahedron. The inner angles of the Euclidean triangle are $\theta(e_i)$'s and the edge lengths of it are $R \sin(\theta(e_i))$ where R is the radius of the circumcircle. Now by lemma 2.4 that $\sin(\theta(e_i)) = c' e^{W(e_i)}$, the lengths of the edges in the triangle are $ce^{W(e_i)}$ for some constant c . Thus the lemma follows from the triangular inequality for edge lengths of triangles.

2.4. A proof of theorem 1.2. Recall that the maximum volume point $p \in \mathbf{A}(\mathbf{T})$ corresponds to a complete hyperbolic metric, i.e., there exists a geodesic triangulation of a complete hyperbolic metric on M so that the triangulation is isotopic to T and the dihedral angles coincide with the angles given by p . Choose small horospheres at the cusp ends of M so that each tetrahedron becomes an ideal decorated hyperbolic tetrahedron. In particular, each edge e in \mathbf{T} has a the edge

length $L(e)$ (in the decorated tetrahedra). For each $i = (e, \sigma) \in I$, we define the average length w_i (of e in σ) to be

$$(2.10) \quad w_i = \frac{1}{2}(L(e) + L(e'))$$

where e, e' are opposite edges in σ .

Lemma 2.6. *We have*

$$(2.11) \quad \sum_{i \notin J} a_i \ln |\sin(p_i)| = \sum_{i \notin J} a_i w_i.$$

PROOF. A tetrahedron σ is called flat (in p) if its dihedral angles in p are $0, 0, \pi$, i.e., there is $i \in I$ with $i < \sigma$. If σ is not flat, then by lemma 2.4, there is a constant $c(\sigma)$ so that (2.6) holds for each pair of opposite edges e, e' . This is the same as

$$(2.12) \quad w_i = \ln |\sin(p_i)| + c(\sigma)$$

for $i < \sigma$. Multiply (2.12) by a_i and sum over all not flat tetrahedra, we obtain

$$(2.13) \quad \sum_{i \notin J} a_i w_i = \sum_{i \notin J} a_i \ln |\sin(p_i)| + \sum_{i \notin J, i < \sigma} a_i c(\sigma).$$

But

$$\sum_{i \notin J, i < \sigma} a_i c(\sigma) = \sum_{\sigma \text{ not flat}} c(\sigma) \left(\sum_{i < \sigma} a_i \right) = 0$$

due to lemma 2.2 (1). This ends the proof. \square

On the other hand, we have

$$(2.14) \quad \sum_{i \in I} a_i w_i = 0.$$

Indeed, if $i = (e, \sigma)$ and $j = (e', \sigma)$ where e, e' are opposite edges in σ , then $a_i = a_j$ and $w_i = w_j$. Furthermore by (2.10), $a_i w_i + a_j w_j = a_i L(e) + a_j L(e')$. Thus

$$\begin{aligned} \sum_{i \in I} a_i w_i &= \sum_{i \in I} a_i \left(\sum_{e < i} L(e) \right) \\ &= \sum_{e \in E} L(e) \left(\sum_{i < e} a_i \right) \\ &= 0 \end{aligned}$$

due to lemma 2.2 (2).

By combining (2.11) and (2.14), we obtain

$$(2.15) \quad \sum_{i \notin J} a_i \ln |\sin(p_i)| = - \sum_{i \in J} a_i w_i.$$

By (2.15), we can rewrite (2.5) as,

$$\begin{aligned} \lim_{t \rightarrow 0^+} f'(t) &= -\frac{1}{2} \left(\sum_{i \in J} a_i \ln |a_i| + \sum_{i \in J} a_i w_i \right) \\ &= \sum_{\sigma \text{ is flat}} (-a_i \ln |a_i| - a_j \ln |a_j| - a_k \ln |a_k| + a_i w_i + a_j w_j + a_k w_k) \end{aligned}$$

where $i, j, k < \sigma$, $\{i, j, k\} \in \Delta$.

Since σ is flat, we may assume that $p_k = \pi$, $p_i = p_j = 0$. Then by lemma 2.5, three average lengths w_i, w_j, w_k satisfy the triangular equality, i.e., $e^{w_k} = e^{w_i} + e^{w_j}$. Furthermore, $a_i \geq 0$, $a_j \geq 0$ and $a_i + a_j + a_k = 0$.

We claim

$$(2.16) \quad -a_i \ln |a_i| - a_j \ln |a_j| - a_k \ln |a_k| + a_i w_i + a_j w_j + a_k w_k \leq 0.$$

Evidently, (2.16) implies that $\lim_{t \rightarrow 0^+} f'(t) \leq 0$. Now (2.16) follows from the following simple lemma on a convex function where we take $x = a_i, y = a_j, z = a_k, a = w_i, b = w_j, c = w_k$.

Lemma 2.7. *Suppose $x, y, a, b, c \in \mathbf{R}_{\geq 0}$, $x + y + z = 0$ and $e^c \geq e^a + e^b$. Then*

$$(2.17) \quad -x \ln x - y \ln y - z \ln z + ax + by + cz \leq 0.$$

We remark that if $e^c = e^a + e^b$, then the inequality becomes equality for some non-zero x, y, z .

PROOF. Replacing $z = -x - y$, we obtain the equivalent form of (2.17) as

$$(x + y) \ln(x + y) - x \ln x - y \ln y \leq (c - a)x + (c - b)y.$$

The above inequality is homogeneous in (x, y) , i.e., it is equivalent if we replace (x, y) by $(\lambda x, \lambda y)$ where $\lambda > 0$. Thus we may assume further that $y = 1$. Thus it remains to prove,

$$(2.18) \quad (x + 1) \ln(x + 1) - x \ln x \leq (c - a)x + (c - b)$$

for all $x \geq 0$. Let $g(x) = (x + 1) \ln(x + 1) - x \ln x$. Then $g'(x) = \ln(1 + \frac{1}{x})$ and $g''(x) = -\frac{1}{x(1+x)}$. It follows that $g''(x) \leq 0$, i.e., g is concave in $[0, \infty)$. The equation of the tangent line to g at the point $x_0 = \frac{e^a}{e^c - e^a}$ is $y = h(x)$ where

$$h(x) = (c - a)x + (c - \ln(e^c - e^a)).$$

Since g is concave, we have $g(x) \leq h(x)$. Now use $b \geq \ln(e^c - e^a)$, we obtain $h(x) \leq (c - a)x + (c - b)$. Thus lemma follows. \square
